

GAME PLAYING AND ADVERSARIAL SEARCH

CHAPTER 5, SECTIONS 1–5

Outline

- ◇ Perfect play
- ◇ Resource limits
- ◇ α - β pruning
- ◇ Games of chance

Games vs. search problems

“Unpredictable” opponent \Rightarrow solution is a contingency plan

Time limits \Rightarrow unlikely to find goal, must approximate

Plan of attack:

- algorithm for perfect play (Von Neumann, 1944)
- finite horizon, approximate evaluation (Zuse, 1945; Shannon, 1950; Samuel, 1952–57)
- pruning to reduce costs (McCarthy, 1956)

Types of games

	deterministic	chance
perfect information	chess, checkers, go, othello	backgammon monopoly
imperfect information		bridge, poker, scrabble nuclear war

Representing a game as a search problem

We can formally define a strategic two-player game by:

- initial state
- actions
- terminal test (i.e. win / lose / draw)
- utility function (i.e. numeric reward for outcome)
 - chess: +1, 0, -1
 - poker: cash won or lost

In a zero-sum game with 2 players:
each player's utility for a state are equal and opposite

Minimax

Perfect play for deterministic, perfect-information games

Idea: choose move to position with highest *minimax value*
= best achievable payoff against best play

E.g., 2-ply game:

Minimax algorithm

function MINIMAX-DECISION(*game*) *returns an operator*

for each *op* **in** OPERATORS[*game*] **do**

 VALUE[*op*] \leftarrow MINIMAX-VALUE(APPLY(*op*, *game*), *game*)

end

return the *op* with the highest VALUE[*op*]

function MINIMAX-VALUE(*state*, *game*) *returns a utility value*

if TERMINAL-TEST[*game*](*state*) **then**

return UTILITY[*game*](*state*)

else if MAX is to move in *state* **then**

return the highest MINIMAX-VALUE of SUCCESSORS(*state*)

else

return the lowest MINIMAX-VALUE of SUCCESSORS(*state*)

Properties of minimax

Complete??

Optimal??

Time complexity??

Space complexity??

Properties of minimax

Complete?? Yes, if tree is finite (chess has specific rules for this)

Optimal?? Yes, against an optimal opponent. Otherwise??

Time complexity?? $O(b^m)$

Space complexity?? $O(bm)$ (depth-first exploration)

For chess, $b \approx 35$, $m \approx 100$ for “reasonable” games
 \Rightarrow exact solution completely infeasible

Resource limits

Suppose we have 100 seconds, explore 10^4 nodes/second
 \Rightarrow 10^6 nodes per move

Standard approach:

- *cutoff test*
e.g., depth limit (perhaps add *quiescence search*)
- *evaluation function*
= estimated desirability of position

Evaluation functions

Black to move

White slightly better

White to move

Black winning

For chess, typically *linear* weighted sum of features

$$\text{EVAL}(s) = w_1 f_1(s) + w_2 f_2(s) + \dots + w_n f_n(s)$$

e.g., $w_1 = 9$ with

$f_1(s) = (\text{number of white queens}) - (\text{number of black queens})$

etc.

Digression: Exact values don't matter

Behaviour is preserved under any *monotonic* transformation of EVAL

Only the order matters:

payoff in deterministic games acts as an *ordinal utility* function

Cutting off search

MINIMAXCUTOFF is identical to MINIMAXVALUE except

1. TERMINAL? is replaced by CUTOFF?
2. UTILITY is replaced by EVAL

Does it work in practice?

$$b^m = 10^6, \quad b = 35 \quad \Rightarrow \quad m = 4$$

4-ply lookahead is a hopeless chess player!

4-ply \approx human novice

8-ply \approx typical PC, human master

12-ply \approx IBM's Deep Blue, Kasparov

α - β pruning example

α - β pruning example

α - β pruning example

α - β pruning example

α - β pruning example

Properties of α - β

Pruning *does not* affect final result

Good move ordering improves effectiveness of pruning

With “perfect ordering,” time complexity = $O(b^{m/2})$

⇒ *doubles* depth of search

⇒ can easily reach depth 8 and play good chess

A simple example of the value of reasoning about which computations are relevant (a form of *metareasoning*)

Why is it called α - β ?

α is the best value (to MAX) found so far off the current path

If V is worse than α , MAX will avoid it \Rightarrow prune that branch

Define β similarly for MIN

The α - β algorithm

Basically MINIMAX + keep track of α , β + prune

function MAX-VALUE(*state*, *game*, α , β) **returns** the minimax value of *state*

inputs: *state*, current state in game

game, game description

α , the best score for MAX along the path to *state*

β , the best score for MIN along the path to *state*

if CUTOFF-TEST(*state*) **then return** EVAL(*state*)

for each *s* **in** SUCCESSORS(*state*) **do**

$\alpha \leftarrow \text{MAX}(\alpha, \text{MIN-VALUE}(s, \text{game}, \alpha, \beta))$

if $\alpha \geq \beta$ **then return** β

end

return α

function MIN-VALUE(*state*, *game*, α , β) **returns** the minimax value of *state*

if CUTOFF-TEST(*state*) **then return** EVAL(*state*)

for each *s* **in** SUCCESSORS(*state*) **do**

$\beta \leftarrow \text{MIN}(\beta, \text{MAX-VALUE}(s, \text{game}, \alpha, \beta))$

if $\beta \leq \alpha$ **then return** α

end

return β

Some drawbacks of α - β pruning

- ◇ It is in most cases not feasible to search the entire game tree, a depth limit needs to be set.
- ◇ Alpha-Beta is designed to select a good move but it also calculates the values of all legal moves.

A better method maybe to use what is called the *utility of a node expansion*. In this way a good search algorithm could select a node that had a high utility to expand (these will hopefully lead to better moves). This could lead to a faster decision by searching through a smaller decision space. An extension on those abilities would be the use of another technique called *goal-directed reasoning*. This technique focuses on having a certain goal in mind like capturing the queen in chess.

Deterministic games in practice

Checkers: Chinook ended 40-year-reign of human world champion Marion Tinsley in 1994. Used an endgame database defining perfect play for all positions involving 8 or fewer pieces on the board, a total of 443,748,401,247 positions.

Chess: Deep Blue defeated human world champion Gary Kasparov in a six-game match in 1997. Deep Blue searches 200 million positions per second, uses very sophisticated evaluation, and undisclosed methods for extending some lines of search up to 40 ply.

Othello: human champions refuse to compete against computers, who are too good.

Go: human champions refuse to compete against computers, who are too bad. In go, $b > 300$, so most programs use random moves initially, along with pattern knowledge bases to suggest plausible moves.

Nondeterministic games

E..g, in backgammon, the dice rolls determine the legal moves

Simplified example with coin-flipping instead of dice-rolling:

Algorithm for nondeterministic games

EXPECTIMINIMAX gives perfect play

Just like MINIMAX, except we must also handle chance nodes:

...

if *state* is a chance node **then**

return average of EXPECTIMINIMAX-VALUE of SUCCESSORS(*state*)

...

A version of α - β pruning is possible
but only if the leaf values are bounded. Why??

Nondeterministic games in practice

Dice rolls increase b : 21 possible rolls with 2 dice

Backgammon \approx 20 legal moves (can be 6,000 with 1-1 roll)

$$\text{depth } 4 = 20 \times (21 \times 20)^3 \approx 1.2 \times 10^9$$

As depth increases, probability of reaching a given node shrinks

\Rightarrow value of lookahead is diminished

α - β pruning is much less effective

TDGAMMON uses depth-2 search + very good EVAL

\approx world-champion level

Digression: Exact values DO matter

Behaviour is preserved only by *positive linear* transformation of EVAL

Hence EVAL should be proportional to the expected payoff

Summary

Games illustrate several important points about AI

- ◇ perfection is unattainable \Rightarrow must approximate and make trade-offs
- ◇ uncertainty limits the value of look-ahead
- ◇ can programs learn for themselves as they play? (stay tuned...)

Examples of skills expected:

- ◇ Demonstrate operation of game search algorithms
- ◇ Discuss and evaluate the properties of game search algorithms
- ◇ Design suitable evaluation functions for a game
- ◇ Explain how to search in nondeterministic games
